

# Schrödinger's hats

## A puzzle about parities and permutations

Matthew Brecknell

April 12, 2017

Meet Schrödinger, who travels the world with an unusually clever clowder of  $n$  talking cats. In their latest show, the cats stand in a line. Schrödinger asks a volunteer to take  $n + 1$  hats, numbered zero to  $n$ , and randomly assign one to each cat, so that there is one spare. Each cat sees all of the hats in front of it, but not its own hat, nor those behind, nor the spare hat. The cats then take turns, each calling out a single number from the set  $\{i \mid 0 \leq i \leq n\}$ , without repeating any number previously called, and without any other communication. Although the first call is allowed to be wrong, the remaining cats always call out the numbers on their own hats.

## 1 Introduction

In this article, we will figure out how the cats do this. We'll start with some informal analysis, deriving the solution by repeatedly asking ourselves the question: if there is a solution, what must it look like? Once we've identified the key ingredient of the solution, we'll turn to formal proof in Isabelle/HOL, ultimately showing that the method always works.

Along the way, we'll rediscover a fundamental property of permutation groups, and we'll look at some of the basic techniques of formal mathematical proof.

## 2 Initial observations

We can begin to structure our thinking by making some initial observations.

### 2.1 Order of calls

The rules require each cat to make exactly one call, but do not specify the order in which they do this. We will choose the order which makes best use of available information. The order of calls cannot change what is visible to each cat, so we are only interested in maximising the value of audible information.

It might seem that audible information can flow from any cat to any other cat, but in fact it only travels forwards. When a cat makes a call, all of the information available to it is already known to all the cats behind it. Therefore, cats towards the rear cannot learn anything from the choices made by cats towards the front.

However, cats towards the front *can* learn things from choices made by cats towards the rear, because those choices can encode knowledge of hats which are not visible from the front.

We therefore propose that the cats should take turns from the rearmost towards the front. This maximises the audible information available to each cat at the time it makes its choice.

## 2.2 Limited information

Each cat sees the hats in front of it, and hears the calls made by those behind it, but otherwise receives no information. In particular, no cat knows the rearmost cat's number. Until Schrödinger reveals it at the end of the performance, it could be either of the two hats that are invisible to all cats.

To guarantee success, the cats must therefore assume the worst: that the rearmost cat got it wrong. But this means that all the other cats *must* get it right!

Surprisingly, knowing which cats must get it right makes our job easier. When considering how some cat  $k$  makes its choice, we can assume that all the cats  $\{i \mid 0 < i < k\}$ , i.e. those behind it, except the rearmost, have already made the right choices.

This might seem like circular reasoning, but it's not. In principle, we build up what we know from the rearmost cat, one cat at a time towards the front, using what we've already shown about cats  $\{i \mid 0 \leq i < k\}$  when we're proving that cat  $k$  makes the right choice. Mathematical induction merely says that if all steps are alike, we can take them all at once by considering an arbitrary cat  $k$ , and assuming we've already considered all the cats  $\{i \mid 0 \leq i < k\}$  behind it.

## 2.3 Candidate selection

According to the rules, no cat may repeat a number already called by another cat behind it. With a little thought, we can also say that no cat may call a number that it can see ahead of it. If it did, there would be at least two incorrect calls.

To see this, suppose some cat  $k$  called out a number that it saw on the hat of  $t$  who is in front of  $k$ . Hat numbers are unique, so  $k$ 's number must be different from  $t$ 's, and therefore  $k$ 's call is wrong. But  $t$  may not repeat the number that  $k$  called, so  $t$  is also wrong.

This means that each cat  $k$  has to choose between exactly two candidate numbers: those left over after removing all the numbers it has seen and heard. Since none of the cats  $\{i \mid 0 \leq i < k\}$  previously called  $k$ 's number,  $k$ 's own number is one of those candidates. Taking into account our assumption that all those  $\{i \mid 0 < i < k\}$  except the rearmost, called their own numbers, we can also say that the other candidate will be the same number which the rearmost cat chose *not* to call.

To solve the puzzle, we therefore just need to ensure that every cat  $k$  rejects the same number that the rearmost cat rejected.

This bears repeating, lest we miss its significance!

Working from the rear to the front, if each cat rejects all the numbers it has heard and seen, and of the remaining numbers, *additionally rejects the same number as the rearmost cat*, then the puzzle is solved.

## 3 The choice function

We'll now derive the method the cats use to ensure all of them reject the same hat. We assume that the cats have agreed beforehand on the algorithm each cat will *individually* apply, and have convinced themselves that the agreed algorithm will bring them *collective* success, no matter how the hats are assigned to them.

We can represent the individual algorithm as a function of the information an individual cat receives. We don't yet know its definition, but we can write its type:

```
type_synonym choice = "nat list  $\Rightarrow$  nat list  $\Rightarrow$  nat"
```

That is, when it is cat  $k$ 's turn, we give the list of calls heard from behind, and the list of hats seen in front, both in order, and the function returns the number the cat should call. Incidentally, the lengths of the lists give the position of the cat in the line, so we can use a single function to represent the choices of all cats, without loss of generality.

Given only the hat numbers that were heard and seen, the choice function must first calculate the choice candidates, by reconstructing the set of all hat numbers, and subtracting those  $xs$  that were either heard or seen:

**definition**

```
  candidates :: "nat list  $\Rightarrow$  nat set"
```

**where**

```
  "candidates xs  $\equiv$  {0 .. 1 + length xs} - set xs"
```

We'll now partially implement the choice function, deferring most of the work to a classification function, which we'll take as a parameter until we know how to implement it:

```
type_synonym classifier = "nat  $\Rightarrow$  nat list  $\Rightarrow$  nat  $\Rightarrow$  nat list  $\Rightarrow$  bool"
```

**definition**

```
  choice' :: "classifier  $\Rightarrow$  choice"
```

**where**

```
  "choice' classify heard seen  $\equiv$ 
    case sorted_list_of_set (candidates (heard @ seen)) of
      [a,b]  $\Rightarrow$  if (classify a heard b seen) then b else a"
```

Here, we take the *candidates*, and pass them to the classifier, along with the original arguments *heard* and *seen*.

The order in which we pass these arguments is suggestive of one of the two possible orderings of the full set of hats consistent with what is *heard* and *seen* by the cat making the choice. The cat imagines hat  $b$  on its head, between those it has *heard* and *seen*, and imagines hat  $a$  placed on the floor behind the rearmost cat.

The classifier then returns a *bool* that indicates whether the given ordering should be accepted or rejected. If accepted, the cat calls the hat it had imagined on its own head. If rejected, it calls the other. Since there must always be exactly one correct call, we require that the classifier accepts an ordering if and only if it would reject the alternative:

**definition**

```
  classifier_correct :: "classifier  $\Rightarrow$  bool"
```

**where**

```
  "classifier_correct classify  $\equiv$ 
     $\forall$  a heard b seen.
      classify a heard b seen  $\longleftrightarrow \neg$  classify b heard a seen"
```

This means that we can say which is the accepted ordering, regardless of which ordering we actually passed to the classifier.

Although the refinement from choice to classifier might seem trivial, it gives us a different way of looking at the problem. Instead of asking what is the correct hat number, which is different for each

cat, we can consider orderings of the complete set of hats, and whether or not those orderings are consistent with the information available to *all* of the cats.

In particular, we notice that for all but the rearmost cat to choose the correct hats, the accepted orderings must be the same for all cats. This is because the correct call for any cat must be what was *seen* by all cats to the rear, and will also be *heard* by all cats towards the front.

Surprisingly, this is true even for the rearmost cat! The only thing special about the rearmost cat is that its assigned number is irrelevant. The task of the rearmost cat is not to guess its assigned number, but to inform the other cats which ordering is both consistent with the information they will have, and also accepted by the classifier.

We can write down the required property that the accepted orderings must be consistent:

**definition**

```
"accepted_order_consistent classify ≡
  ∀ a heard b seen a' heard' b' seen'.
    a # heard @ b # seen = a' # heard' @ b' # seen'
  → classify a heard b seen = classify a' heard' b' seen'"
```

So far, we have investigated some properties that the classifier must have, but have not thrown away any information. The classifier is given everything known to each cat. The lengths of the arguments *heard* and *seen* encode the cat's position in the line, so we even allow the classifier to behave differently for each cat.

But the property *accepted\_order\_consistent* suggests that the position in the line is not needed, and that we can collapse the classifier's arguments into a single list. Given an existing classifier, we can define a function which does this:

```
type_synonym parity = "nat list ⇒ bool"
```

**definition**

```
parity :: "classifier ⇒ parity"
where
  "parity classify xs ≡
    case xs of x # y # zs ⇒ classify x [] y zs | _ ⇒ True"
```

We can prove that it has all the behaviours of a well-defined classifier, which means that, in fact, we have not thrown away anything:

**lemma parity\_complete:**

```
"accepted_order_consistent classify ⇒
  ∀ a heard b seen. classify a heard b seen = parity classify (a # heard @ b # seen)"
unfolding accepted_order_consistent_def parity_def
apply (intro allI)
apply (drule_tac x=a in spec)
apply (drule_tac x=heard in spec)
apply (drule_tac x=b in spec)
apply (drule_tac x=seen in spec)
apply (case_tac heard)
by auto
```

## 4 Proof

### 4.1 Parity of a list permutation

Define the parity of a list  $xs$  as the evenness of the number of inversions. Count an inversion for every pair of indices  $i$  and  $j$ , such that  $i < j$ , but  $xs!i > xs!j$ .

```
primrec
  parity :: "nat list  $\Rightarrow$  bool"
where
  "parity [] = True"
| "parity (x # ys) = (parity ys = even (length [y  $\leftarrow$  ys. x > y]))"
```

In a list that is sufficiently distinct, swapping any two elements inverts the `parity`.

```
lemma parity_swap_adj:
  "b  $\neq$  c  $\implies$  parity (as @ b # c # ds)  $\longleftrightarrow$   $\neg$  parity (as @ c # b # ds)"
  by (induct as) auto
```

```
lemma parity_swap:
  assumes "b  $\neq$  d  $\wedge$  b  $\notin$  set cs  $\wedge$  d  $\notin$  set cs"
  shows "parity (as @ b # cs @ d # es)  $\longleftrightarrow$   $\neg$  parity (as @ d # cs @ b # es)"
  using assms
  proof (induct cs arbitrary: as)
    case Nil thus ?case using parity_swap_adj[of b d as es] by simp
  next
    case (Cons c cs) show ?case
      using parity_swap_adj[of b c as "cs @ d # es"]
        parity_swap_adj[of d c as "cs @ b # es"]
        Cons(1)[where as="as @ [c]"] Cons(2)
      by simp
  qed
```

### 4.2 Solving the puzzle

#### 4.2.1 Individual choice function

Given a list of all hat numbers either *seen* or *heard*, we can reconstruct the set of all hat numbers from the length of that list. Excluding the members from the

```
definition
  "candidates xs  $\equiv$  {0 .. 1 + length xs} - set xs"
```

```
definition
  choice :: "nat list  $\Rightarrow$  nat list  $\Rightarrow$  nat"
where
  "choice heard seen  $\equiv$ 
    case sorted_list_of_set (candidates (heard @ seen)) of
      [a,b]  $\Rightarrow$  if parity (a # heard @ b # seen) then b else a"
```

#### 4.2.2 Group choice function

```
primrec
  choices' :: "nat list  $\Rightarrow$  nat list  $\Rightarrow$  nat list"
```

```

where
  "choices' heard [] = []"
| "choices' heard (_ # seen)
  = (let c = choice heard seen in c # choices' (heard @ [c]) seen)"

definition "choices  $\equiv$  choices' []"

```

### 4.2.3 Examples

```

definition "example_even  $\equiv$  [4,2,3,6,0,5]"
lemma "parity (1 # example_even)" by eval
lemma "choices example_even = [4,2,3,6,0,5]" by eval

definition "example_odd  $\equiv$  [4,0,3,6,2,5]"
lemma " $\neg$  parity (1 # example_odd)" by eval
lemma "choices example_odd = [1,0,3,6,2,5]" by eval

```

### 4.2.4 Group choice does not cheat

```

lemma choices':
  assumes "i < length assigned"
  assumes "spoken = choices' heard assigned"
  shows "spoken ! i = choice (heard @ take i spoken) (drop (Suc i) assigned)"
  using assms proof (induct assigned arbitrary: i spoken heard)
    case Cons thus ?case by (cases i) (auto simp: Let_def)
  qed simp

lemma choices:
  assumes "i < length assigned"
  assumes "spoken = choices assigned"
  shows "spoken ! i = choice (take i spoken) (drop (Suc i) assigned)"
  using assms by (simp add: choices_def choices')

```

### 4.2.5 Group choice has the correct length

```

lemma choices'_length: "length (choices' heard assigned) = length assigned"
  by (induct assigned arbitrary: heard) (auto simp: Let_def)

lemma choices_length: "length (choices assigned) = length assigned"
  by (simp add: choices_def choices'_length)

```
