

Schrödinger's hats

A puzzle about parities and permutations

Matthew Brecknell

April 20, 2017

Meet Schrödinger, who travels the world with an unusually clever clowder of n talking cats. In their latest show, the cats stand in a line. Schrödinger asks a volunteer to take $n + 1$ hats, numbered zero to n , and randomly assign one to each cat, so that there is one spare. Each cat sees all of the hats in front of it, but not its own hat, nor those behind, nor the spare hat. The cats then take turns, each saying a single number from the set $\{i \mid 0 \leq i \leq n\}$, without repeating any number said previously, and without any other communication. The cats are allowed a single incorrect guess, but otherwise every cat must say the number on its own hat.

1 Introduction

In this article, we will figure out how the cats do this. We'll start with some informal analysis, deriving the solution by asking what properties it must have, and refining these properties until we can realise them with a concrete algorithm. We'll also develop a formal proof in Isabelle/HOL that the method always works.

Along the way, we'll rediscover a fundamental property of permutation groups, and we'll gain some familiarity with basic tools of formal mathematical proof.

For the informal analysis, we'll work from the top down, so you can see the solution unfold gradually. Each refinement will be small, and may seem like it is the only possible step.

We would like to use Isabelle/HOL to make our informal analysis more precise. However, our proof is inherently bottom up, from the solution we ultimately identify to a theorem that it solves the puzzle.

So, to allow us to develop the proof as we work top down, we need to turn the proof upside down. We'll do this by temporarily assuming things we believe must be true for the puzzle to have a solution, but which we don't yet know how to prove. To avoid repeating assumptions, we'll use the *locale* mechanism of Isabelle/HOL to create named bundles of assumptions. Later, we'll discharge assumptions using the locale *interpretation* mechanism.

To illustrate, we can use a locale to describe the basic setup of the puzzle:

```
locale hats =  
  — the spare hat  
  fixes spare :: "nat"  
  — hats assigned to cats, in order from back to front  
  fixes assigned :: "nat list"  
  — the set of all hat numbers  
  assumes assign: "set (spare # assigned) = {0 .. length assigned}"
```

In this locale, we can use a cardinality argument to prove that the hats are numbered distinctly:

```
lemma (in hats) distinct: "distinct (spare # assigned)"
  apply (rule card_distinct)
  apply (subst assign)
  by auto
```

The proof developed this way turns out to be more convoluted than it needs to be, so the appendix contains a version of the proof written in a more direct style.

2 Initial observations

We can begin to structure our thinking by making some initial observations.

2.1 Ordering the calls

The rules require each cat to make exactly one call, but do not specify the order in which they do this. We can see that the order we choose affects the distribution of information:

- Visible information remains constant over time, but cats towards the rear see more than cats towards the front.
- Audible information accumulates over time, but at any particular point in time, all cats have heard the same things.

We observe that the cats can only ever communicate information *forwards*, never backwards:

- When a cat chooses a number, all of the information available to it is already known to all the cats behind it. Therefore, cats towards the rear can never learn anything from the choices made by cats towards the front.
- However, cats towards the front *can* learn things from choices made by cats towards the rear, because those choices might encode knowledge of hats which are not visible from the front.

We propose that the cats should take turns from the rearmost towards the front, ensuring that:

- The cat making the choice is always the one with the most information.
- We maximise the amount each cat can learn before it makes its choice.

We'll use a locale to describe the information flow:

```
locale cats = hats +
  — numbers spoken by cats, in order from back to front
  fixes spoken :: "nat list"
  — each cat speaks exactly once
  assumes length: "length spoken = length assigned"
```

```
definition (in cats) "heard k  $\equiv$  take k spoken"
```

```
definition (in cats) "seen k  $\equiv$  drop (Suc k) assigned"
```

2.2 The rearmost cat is special

Each cat sees the hats in front of it, and hears the calls made by those behind it, but otherwise receives no information. In particular, no cat knows the rearmost cat's number. Until Schrödinger reveals it at the end of the performance, it could be either of the two hats that are invisible to all cats.

To guarantee success, the cats must therefore assume the worst: that the rearmost cat got it wrong. But this means that all the other cats *must* get it right!

2.3 Reasoning by induction

Knowing which cats must get it right makes our job easier, since we don't need to keep track of whether the cats have used up their free pass. When considering how some cat k makes its choice, we can assume that all the cats $\{i \mid 0 < i < k\}$, i.e. those behind it, except the rearmost, have already made the right choices.

This might seem like circular reasoning, but it's not. In principle, we build up what we know from the rearmost cat, one cat at a time towards the front, using what we've already shown about cats $\{i \mid 0 \leq i < k\}$ when we're proving that cat k makes the right choice. Mathematical induction merely says that if all steps are alike, we can take an arbitrary number of them all at once, by considering an arbitrary cat k , and assuming we've already considered all the cats $\{i \mid 0 \leq i < k\}$ behind it. We'll use a locale to package the induction hypothesis:

```

locale cat_k = cats +
  fixes k :: "nat"
  assumes k_min: "0 < k"
  assumes k_max: "k < length assigned"
  assumes IH: " $\forall i \in \{1 \dots k\}. \text{spoken } ! i = \text{assigned } ! i$ "

lemma (in cats) cat_k_induct:
  assumes " $\bigwedge k. \text{cat\_k spare assigned spoken } k \implies \text{spoken } ! k = \text{assigned } ! k$ "
  shows " $k \in \{1 \dots \text{length assigned}\} \implies \text{spoken } ! k = \text{assigned } ! k$ "
  apply (induct k rule: nat_less_induct)
  apply (rule assms)
  apply (unfold_locales)
  by auto

lemma (in cat_k) k_max_spoken: "k < length spoken"
  using k_max length by simp

lemma (in cat_k) heard_k:
  " $\text{heard } k = \text{spoken } ! 0 \# \text{map } (\text{op } ! \text{ assigned}) [\text{Suc } 0 \dots k]$ "
  using heard_def[of k] IH
    take_map_nth[OF less_imp_le, OF k_max_spoken]
    range_extract_head[OF k_min]
  by auto

```

2.4 Candidate selection

According to the rules, no cat may repeat a number already said by another cat behind it. With a little thought, we can also say that no cat may call a number that it can see ahead of it. If it did, there would be at least two incorrect calls.

To see this, suppose some cat k said a number that it saw on the hat of t who is in front of k . Hat numbers are unique, so k 's number must be different from t 's, and therefore k 's choice is wrong. But t may not repeat the number that k said, so t is also wrong.

Each cat k therefore has to choose between exactly two candidate hats: those left over after excluding all the numbers it has seen and heard:

```

definition
  candidates_excluding :: "nat list  $\Rightarrow$  nat list  $\Rightarrow$  nat set"
where
  "candidates_excluding heard seen  $\equiv$ 
    let excluded = heard @ seen in {0 .. 1 + length excluded} - set excluded"

definition (in cats)
  "candidates k  $\equiv$  candidates_excluding (heard k) (seen k)"

lemma (in cats) candidates_i:
  fixes a b i
  defines v: "view  $\equiv$  (a # heard i @ b # seen i)"
  assumes i: "i < length assigned"
  assumes d: "distinct view"
  assumes s: "set view = {0..length assigned}"
  shows "candidates i = {a,b}"
proof -
  let ?excluded = "heard i @ seen i"
  have len: "1 + length ?excluded = length assigned"
    unfolding heard_def seen_def using i length by auto
  have set: "set ?excluded = {0..length assigned} - {a,b}"
    apply (rule subset_minusI)
    using s d unfolding v by auto
  show ?thesis
    unfolding candidates_def candidates_excluding_def Let_def
    unfolding len set
    unfolding Diff_Diff_Int subset_absorb_r
    using s unfolding v
    by auto
qed

```

Since none of the cats $\{i \mid 0 \leq i < k\}$ previously said k 's number, k 's own number is one of those candidates. Taking into account our assumption that all those $\{i \mid 0 < i < k\}$ except the rearmost said their own numbers, we can also say that the other candidate will be the same number which the rearmost cat chose *not* to call.

To solve the puzzle, we therefore just need to ensure that every cat k rejects the same number that the rearmost cat rejected.

To formalise this, we'll first prove that the *candidates* for the rearmost cat are as we expect:

```

locale cat_0 = cats +
  assumes exists_0: "0 < length assigned"

sublocale cat_k < cat_0
  apply unfold_locales
  using k_min k_max
  by auto

lemma (in cat_0) assigned_0: "assigned ! 0 # drop (Suc 0) assigned = assigned"
  using Cons_nth_drop_Suc[OF exists_0] by simp

lemma (in cat_0) candidates_0: "candidates 0 = {spare, assigned ! 0}"
  apply (rule candidates_i[OF exists_0])

```

```

using distinct assign unfolding heard_def seen_def assigned_0
by auto

```

We define the *rejected* has as whichever of those the rearmost cat does not choose:

```

definition (in cat_0)
  "rejected  $\equiv$  if spoken ! 0 = spare then assigned ! 0 else spare"

```

We can try to prove a similar theorem for cat *k*, but we discover that we need some additional assumptions that the expected *candidates*, together with what cat *k* has *heard* and *seen*, constitute the complete set of hats.

We express these assumptions with an abbreviation *view_k*. We'll discharge the assumptions by proving that this is an ordering of the complete set of hats.

We'll prove the assumptions by appealing to two other orderings of the complete set of hats. We'll use *view_0* as a step towards *view_n*. The latter is very close to the ordering used in the original specification of *hats*, so we can easily prove the relevant properties of *view_n*

```

abbreviation (in cat_0) (input) "view_n  $\equiv$  spare # assigned ! 0 # seen 0"
abbreviation (in cat_0) (input) "view_0  $\equiv$  rejected # spoken ! 0 # seen 0"
abbreviation (in cat_k) (input) "view_k  $\equiv$  rejected # heard k @ assigned ! k # seen k"

```

```

lemma (in cat_0)
  distinct_n: "distinct view_n" and
  set_n: "set view_n = {0..length assigned}"
  using distinct assign
  unfolding seen_def assigned_0
  by auto

```

Ordering *view_0* is the same as *view_k*, but seen from the rearmost cat's perspective. We prove they are equal:

```

lemmas (in cat_k) drop_maps =
  drop_map_nth[OF less_imp_le_nat, OF k_max]
  drop_map_nth[OF Suc_leI[OF exists_0]]

lemma (in cat_k) view_eq: "view_0 = view_k"
  unfolding heard_k seen_def
  apply (simp add: k_max Cons_nth_drop_Suc drop_maps)
  apply (subst map_append[symmetric])
  apply (rule arg_cong[where f="map _"])
  apply (rule range_app[symmetric])
  using k_max k_min less_imp_le Suc_le_eq by auto

```

Now, to prove the relevant properties about *view_k*, we just need to prove them for *view_0*. But to do that, we need to know something about *spoken ! 0*. We haven't yet figured out how that choice is made, so we'll just assume it's one of the *candidates*:

```

locale cat_0_spoken = cat_0 +
  assumes spoken_candidate_0: "spoken ! 0  $\in$  candidates 0"

```

```

lemma (in cat_0_spoken)
  distinct_0: "distinct view_0" and
  set_0: "set view_0 = {0..length assigned}"
  using spoken_candidate_0 distinct_n set_n

```

```

unfolding candidates_0 rejected_def
by fastforce+

```

Finally, we can prove the properties we wanted for *view_k*, and use them to discharge the assumptions of *candidates_k*.

```

locale cat_k_view = cat_k + cat_0_spoken

```

```

lemma (in cat_k_view)
  distinct_k: "distinct view_k" and
  set_k: "set view_k = {0..length assigned}"
  using distinct_0 set_0 view_eq
  by auto

```

```

lemma (in cat_k_view) candidates_k: "candidates k = {rejected, assigned ! k}"
  using candidates_i[OF k_max] distinct_k set_k by simp

```

If we additionally assumed that cat *k* chooses one of its *candidates*, but somehow avoids the *rejected* hat, it trivially follows that cat *k* chooses its *assigned* hat.

This bears repeating, lest we miss its significance!

Working from the rear to the front, if each cat rejects all the numbers it has heard and seen, and of the remaining numbers, *additionally rejects the same number as the rearmost cat*, then the puzzle is solved.

3 The choice function

We'll now derive the method the cats use to ensure all of them reject the same hat. We assume that the cats have agreed beforehand on the algorithm each cat will *individually* apply, and have convinced themselves that the agreed algorithm will bring them *collective* success, no matter how the hats are assigned to them.

We can represent the individual algorithm as a function of the information an individual cat receives. We don't yet know its definition, but we can write its type:

```

type_synonym choice = "nat list  $\Rightarrow$  nat list  $\Rightarrow$  nat"

```

That is, when it is cat *k*'s turn, we give the list of calls *heard* from behind, and the list of hats *seen* in front, both in order, and the function returns the number the cat should call. The lengths of the lists give the position of the cat in the line, so we can use a single function to represent the choices of all cats, without loss of generality.

We can partially implement the *choice* function, first calculating the *candidates*, and deferring the remaining work to a *classifier* function, which we'll take as a parameter until we know how to implement it:

```

type_synonym classifier = "nat  $\Rightarrow$  nat list  $\Rightarrow$  nat  $\Rightarrow$  nat list  $\Rightarrow$  bool"

```

```

locale classifier =
  fixes classify :: "classifier"

```

```

definition (in classifier)
  choice :: "choice"
where

```

```

"choice heard seen  $\equiv$ 
  case sorted_list_of_set (candidates_excluding heard seen) of
    [a,b]  $\Rightarrow$  if (classify a heard b seen) then b else a"

primrec (in classifier)
  choices' :: "nat list  $\Rightarrow$  nat list  $\Rightarrow$  nat list"
where
  "choices' heard [] = []"
| "choices' heard _ # seen"
  = (let c = choice heard seen in c # choices' (heard @ [c]) seen)"

definition (in classifier) "choices  $\equiv$  choices' []"

lemma (in classifier) choices':
  assumes "i < length assigned"
  assumes "spoken = choices' heard assigned"
  shows "spoken ! i = choice (heard @ take i spoken) (drop (Suc i) assigned)"
  using assms proof (induct assigned arbitrary: i spoken heard)
    case Cons thus ?case by (cases i) (auto simp: Let_def)
  qed simp

lemma (in classifier) choices:
  assumes "i < length assigned"
  assumes "spoken = choices assigned"
  shows "spoken ! i = choice (take i spoken) (drop (Suc i) assigned)"
  using assms choices' by (simp add: choices_def)

lemma (in classifier) choices'_length: "length (choices' heard assigned) = length assigned"
  by (induct assigned arbitrary: heard) (auto simp: Let_def)

lemma (in classifier) choices_length: "length (choices assigned) = length assigned"
  by (simp add: choices_def choices'_length)

```

The order in which we pass arguments to the `classifier` is suggestive of one of the two possible orderings of the full set of hats consistent with what is `heard` and `seen` by the cat making the choice. We imagine hat `b` on the cat's head, between those it has `heard` and `seen`, and imagine hat `a` placed on the floor behind the rearmost cat, where no cat can see it.

The classifier then returns a `bool` that indicates whether the given ordering should be accepted or rejected. If accepted, the cat calls the hat it had imagined on its own head. If rejected, it calls the other.

Since there must always be exactly one correct call, we require that the classifier accepts an ordering if and only if it would reject the alternative:

```

locale classifier_swap = classifier +
  assumes classifier_swap:
    " $\bigwedge a \text{ heard } b \text{ seen.}$ 
      distinct (a # heard @ b # seen)  $\implies$ 
        classify a heard b seen  $\longleftrightarrow \neg$  classify b heard a seen"

```

This means that we can say which is the accepted ordering, regardless of which ordering we actually passed to the classifier.

Although its a small refinement from choice to classifier, it gives us a different way of looking at the

problem. Instead of asking what is the correct hat number, which is different for each cat, we can consider orderings of the complete set of hats, and whether or not those orderings are consistent with the information available to *all* of the cats.

In particular, we notice that for all but the rearmost cat to choose the correct hats, the accepted orderings must be the same for all cats. This is because the correct call for any cat must be what was *seen* by all cats to the rear, and will also be *heard* by all cats towards the front.

Surprisingly, this is true even for the rearmost cat! The only thing special about the rearmost cat is that its assigned number is irrelevant. The task of the rearmost cat is not to guess its assigned number, but to inform the other cats which ordering is both consistent with the information they will have, and also accepted by the classifier.

We can write down the required property that the accepted orderings must be consistent:

```
locale classifier_consistent = classifier_swap +
  assumes classifier_consistent:
    " $\bigwedge a \text{ heard } b \text{ seen } a' \text{ heard } b' \text{ seen}.$ 
       $a \# \text{heard } @ \ b \# \text{seen} = a' \# \text{heard } @ \ b' \# \text{seen}$ 
       $\implies \text{classify } a \text{ heard } b \text{ seen} = \text{classify } a' \text{ heard } b' \text{ seen}''$ "
```

So far, we have investigated some properties that a *classifier* must have, but have not thrown away any information. The classifier is given everything known to each cat. The lengths of the arguments *heard* and *seen* encode the cat's position in the line, so we even allow the classifier to behave differently for each cat.

But the property *classifier_well_behaved* suggests that the position in the line is redundant, and we can collapse the classifier's arguments into a single list.

```
type_synonym parity = "nat list  $\Rightarrow$  bool"
```

```
locale parity_classifier =
  fixes parity :: "parity"
  assumes parity_swap_0_i:
    " $\bigwedge a \text{ heard } b \text{ seen}.$ 
       $\text{distinct } (a \# \text{heard } @ \ b \# \text{seen}) \implies$ 
       $\text{parity } (a \# \text{heard } @ \ b \# \text{seen}) \longleftrightarrow \neg \text{parity } (b \# \text{heard } @ \ a \# \text{seen})''$ "
```

```
sublocale parity_classifier < classifier_consistent " $\lambda a \text{ heard } b \text{ seen}.$   $\text{parity } (a \# \text{heard } @ \ b \# \text{seen})''$ "
  apply (unfold_locales)
  apply (erule parity_swap_0_i)
  by auto
```

Based on the informal derivation so far, our claim is that any function satisfying *parity_correct* is sufficient to solve the puzzle. Let's first prove this is the case, and then finally, we'll derive a *parity* function.

```
locale hats_parity = hats + parity_classifier
```

```
sublocale hats_parity < cats spare assigned "choices assigned"
  using choices_length by unfold_locales

5.1 Solving the puzzle

5.1.1 Individual choice function

Given a list of all hat numbers either *seen* or *heard*, we can reconstruct the set of all hat numbers from the length of that list. Excluding the members from the

definition

```

"candidates xs ≡ {0 .. 1 + length xs} - set xs"

```

definition

```

choice :: "nat list ⇒ nat list ⇒ nat"

```

where

```

"choice heard seen ≡
  case sorted_list_of_set (candidates (heard @ seen)) of
    [a,b] ⇒ if parity (a # heard @ b # seen) then b else a"

```

5.1.2 Group choice function

primrec

```

choices' :: "nat list  $\Rightarrow$  nat list  $\Rightarrow$  nat list"
where
  "choices' heard [] = []"
| "choices' heard (_ # seen)
  = (let c = choice heard seen in c # choices' (heard @ [c]) seen)"

definition "choices  $\equiv$  choices' []"

```

5.1.3 Examples

```

definition "example_even  $\equiv$  [4,2,3,6,0,5]"
lemma "parity (1 # example_even)" by eval
lemma "choices example_even = [4,2,3,6,0,5]" by eval

definition "example_odd  $\equiv$  [4,0,3,6,2,5]"
lemma " $\neg$  parity (1 # example_odd)" by eval
lemma "choices example_odd = [1,0,3,6,2,5]" by eval

```

5.1.4 Group choice does not cheat

```

lemma choices':
  assumes "i < length assigned"
  assumes "spoken = choices' heard assigned"
  shows "spoken ! i = choice (heard @ take i spoken) (drop (Suc i) assigned)"
