# Schrödinger's hats

## A puzzle about parities and permutations

Matthew Brecknell

April 9, 2017

Meet Schrödinger, who travels the world with an unusually clever clowder of n talking cats. In their latest show, the cats stand in a line. Schrödinger asks a volunteer to take n+1 hats, numbered zero to n, and randomly assign one to each cat, so that there is one spare. Each cat sees all of the hats in front of it, but not its own hat, nor those behind, nor the spare hat. The cats then take turns, each calling out a single number from the set  $\{i \mid 0 \le i \le n\}$ , without repeating any number previously called, and without any other communication. Although the first call is allowed to be wrong, the remaining cats always call out the numbers on their own hats.

## 1 Introduction

In this article, we will figure out how the cats do this. We'll start with some informal analysis, deriving the solution by repeatedly asking ourselves the question: if there is a solution, what must it look like? Once we've identified the key ingredient of the solution, we'll turn to formal proof in Isabelle/HOL, ultimately showing that the method always works.

Along the way, we'll rediscover a fundamental property of permutation groups, and we'll look at some of the basic techniques of formal mathematical proof.

## 2 Initial observations

We can begin to structure our thinking by making some initial observations.

## 2.1 Order of calls

The rules require each cat to make exactly one call, but do not specify the order in which they do this. We will choose the order which makes best use of available information. The order of calls cannot change what is visible to each cat, so we are only interested in maximising the value of audible information.

It might seem that audible information can flow from any cat to any other cat, but in fact it only travels forwards. When a cat makes a call, all of the information available to it is already known to all the cats behind it. Therefore, cats towards the rear cannot learn anything from the choices made by cats towards the front.

However, cats towards the front *can* learn things from choices made by cats towards the rear, because those choices can encode knowledge of hats which are not visible from the front.

We therefore propose that the cats should take turns from the rearmost towards the front. This maximises the audible information available to each cat at the time it makes its choice.

#### 2.2 Limited information

Each cat sees the hats in front of it, and hears the calls made by those behind it, but otherwise recieves no information. In particular, no cat knows the rearmost cat's number. Until Schrödinger reveals it at the end of the performance, it could be either of the two hats that are invisible to all cats.

To guarantee success, the cats must therefore assume the worst: that the rearmost cat got it wrong. But this means that all the other cats *must* get it right!

Surprisingly, knowing which cats must get it right makes our job easier. When considering how some cat k makes its choice, we can assume that all the cats  $\{i \mid 0 < i < k\}$ , i.e. those behind it, except the rearmost, have already made the right choices.

This might seem like circular reasoning, but it's not. In principle, we build up what we know from the rearmost cat, one cat at a time towards the front. Mathematical induction merely says that we can do this all at once by considering an arbitrary cat k, and assuming we've already considered all the cats  $\{i \mid 0 \le i < k\}$  behind it.

#### 2.3 Candidate selection

According to the rules, no cat may repeat a number already called by another cat behind it. With a little thought, we can also say that no cat may call a number that it can see ahead of it. If it did, there would be at least two incorrect calls.

To see this, suppose some cat k called out a number that it saw on the hat of t who is in front of k. Hat numbers are unique, so k's number must be different from t's, and therefore k's call is wrong. But t may not repeat the number that k called, so t is also wrong.

This means that each cat k has to choose between exactly two candidate numbers: those left over after removing all the numbers it has seen and heard. Since none of the cats  $\{i \mid 0 \le i < k\}$  previously called k's number, k's own number is one of those candidates. Taking into account our assumption that all those  $\{i \mid 0 < i < k\}$  except the rearmost, called their own numbers, we can also say that the other candidate will be the same number which the rearmost cat chose *not* to call.

To solve the puzzle, we therefore just need to ensure that every cat k rejects the same number that the rearmost cat rejected.

## 3 The choice function

If each cat has an algorithm to choose which number to call, we can represent this as a function. We don't yet know its definition, but we can write its type:

```
type synonym choice_type = "nat list \Rightarrow nat list \Rightarrow nat"
```

When it is cat k's turn, we give the list of calls heard from behind, and the list of hats seen in front, both in order, and the function returns the number the cat should call. Incidentally, the lengths of the lists give the position of the cat in the line, so we can a single function to represent the choices of all cats, without loss of generality.

Given only the hat numbers that were heard and seen, the choice function must first calculate the choice candidates, by reconstructing the set of all hat numbers, and subtracting those xs that were either heard or seen:

#### definition

```
candidates :: "nat list \Rightarrow nat set" where 
 "candidates xs \equiv {0 .. 1 + length xs} - set xs"
```

We can now partially implement the choice function, deferring the real work to a classification function, which we'll take as a parameter until we know how to implement it:

```
type_synonym classifier_type = "nat ⇒ nat list ⇒ nat ⇒ nat list ⇒ bool"

definition
   choice' :: "classifier_type ⇒ choice_type"

where
   "choice' classify heard seen ≡
   case sorted_list_of_set (candidates (heard @ seen)) of
   [a,b] ⇒ if (classify a heard b seen) then b else a"
```

Here, we first use *candidates* to calculate the two numbers from which we must choose. We then take these in sorted order, and pass them to the classifier, along with the original arguments *heard* and *seen* 

## 4 Proof

## 4.1 Parity of a list permutation

Define the parity of a list xs as the evenness of the number of inversions. Count an inversion for every pair of indices i and j, such that i < j, but xs!i > xs!j.

```
primrec
   parity :: "nat list \Rightarrow bool"
where
   "parity [] = True"
| "parity (x # ys) = (parity ys = even (length [y \leftarrow ys. x > y]))"
In a list that is sufficiently distinct, swapping any two elements inverts the parity.
lemma parity_swap_adj:
```

```
"b \neq c \Longrightarrow parity (as @ b # c # ds) \longleftrightarrow ¬ parity (as @ c # b # ds)" by (induct as) auto
```

```
lemma parity_swap:
```

```
assumes "b \neq d \wedge b \notin set cs \wedge d \notin set cs"

shows "parity (as @ b # cs @ d # es) \longleftrightarrow ¬ parity (as @ d # cs @ b # es)"

using assms

proof (induct cs arbitrary: as)

case Nil thus ?case using parity_swap_adj[of b d as es] by simp

next

case (Cons c cs) show ?case

using parity_swap_adj[of b c as "cs @ d # es"]

parity_swap_adj[of d c as "cs @ b # es"]
```

```
Cons(1)[where as="as @ [c]"] Cons(2)
    by simp
\mathbf{qed}
```

## 4.2 Solving the puzzle

#### 4.2.1 Individual choice function

Given a list of all hat numbers either seen or heard, we can reconstruct the set of all hat numbers from the length of that list. Excluding the members from the

```
definition
  "candidates xs \equiv {0 .. 1 + length xs} - set xs"
definition
  choice :: "nat list \Rightarrow nat list \Rightarrow nat"
where
  "choice heard seen \equiv
    case sorted_list_of_set (candidates (heard @ seen)) of
       [a,b] \Rightarrow if parity (a # heard @ b # seen) then b else a"
4.2.2 Group choice function
```

```
primrec
  choices' :: "nat list \Rightarrow nat list \Rightarrow nat list"
where
  "choices' heard [] = []"
| "choices' heard (_ # seen)
    = (let c = choice heard seen in c # choices' (heard @ [c]) seen)"
definition "choices ≡ choices' []"
```

#### 4.2.3 Examples

```
definition "example_even \equiv [4,2,3,6,0,5]"
lemma "parity (1 # example_even)" by eval
lemma "choices example_even = [4,2,3,6,0,5]" by eval
definition "example_odd \equiv [4,0,3,6,2,5]"
lemma "¬ parity (1 # example_odd)" by eval
lemma "choices example_odd = [1,0,3,6,2,5]" by eval
```

## 4.2.4 Group choice does not cheat

```
lemma choices':
 assumes "i < length assigned"
 assumes "spoken = choices' heard assigned"
  shows "spoken ! i = choice (heard @ take i spoken) (drop (Suc i) assigned)"
  using assms proof (induct assigned arbitrary: i spoken heard)
   case Cons thus ?case by (cases i) (auto simp: Let_def)
  qed simp
lemma choices:
  assumes "i < length assigned"
```

```
assumes "spoken = choices assigned"
shows "spoken ! i = choice (take i spoken) (drop (Suc i) assigned)"
using assms by (simp add: choices_def choices')
```

#### 4.2.5 Group choice has the correct length

```
lemma choices'_length: "length (choices' heard assigned) = length assigned"
by (induct assigned arbitrary: heard) (auto simp: Let_def)
lemma choices_length: "length (choices assigned) = length assigned"
by (simp add: choices_def choices'_length)
```

#### 4.3 Correctness of choice function
